1. What are the challenges in formalizing biology today?

Formalization of any kind presumes the prior presence of something concrete and particular. Recognizing this in biology is not easy (Waddington, 1966, 1968–1972, 1974). Many biological phenomena do not have adequate mathematical representations. This is because living systems are deploying logic and semiotics

beyond our conception of mathematics into the domain of computation, which is on its part much richer than the standard Turing machine paradigm. In particular, there are four areas deserving attention with broad impacts in and beyond biology (Root-Bernstein, 2012a):

1. *A theory of self-emergent objects* that can carry out functions within interactive variances of the constituents of living systems: developing models of self-emergent objects (origins of first cells; self-assembly of viruses, etc.) that carry out functions (selecting/rejecting among possible components; minimizing free energy; etc.) while utilizing both continuous and discrete information. Set theory is too abstract to handle such "objects"; they have more structure and other properties than sets and the elements of sets. Therefore self-emergent objects must be defined in a frame where their different qualities can be described. Such a theory should be able to incorporate the work that has been done on understanding hierarchical systems, emergent properties, complexity theory, etc. Its mathematics should therefore be extraordinarily integrative. A subsumptive or specification hierarchy is more general than set theory and could be the first step in this direction.

There are two fundamental issues to be taken in consideration. First, cells are autonomous/autopoietic – they form themselves. Therefore, we need to use a frame in which we can describe self-organizing/self-emergent objects mimicking "cellular life" as evolution of such objects using specifications of the relations between them that do provide rules i) to limit the entry and exit of individual elements, and ii) allow elements to undergo transformations (e.g. metabolism) within the object. A key question to answer here is whether the *self* (the individuum with a distinct identity) is a prerequisite for or a consequence of the self-organization? Second, biological objects (cells) have the variance property.¹ We need a theory that allows the definition of objects that are not characterized by specific numbers, proportions and rates of turnover, excretion and replenishment of the object/cell constituents, but i) by (empirically determined) *variances* (number ranges) within which all of these constituents must exist in order for the living object to function as such (Zadeh, 2000; Kauffman, 2001), and ii) with the *self* being *potentially* associated with these variances.

This "bio-affine" theory must allow the integration of continuous and "grainy"/discrete temporalities for the same "object" simultaneously: a circular relation of i) handling continuous variations of the chemical kinetics, e.g. continuous interactions/flows of elements, while ii) acting on small sets of definable/discrete elements/individuals (calculations of modular probabilities) determined by the chemical kinetics. Also, it should have operators/functions capable of defining *state-sensitive objects*, i.e. to model switching processes between stable states when certain values or variances (within them) are exceeded.

2. *A theory of complementary assembling*: biological systems build and organize themselves based on the principle of molecular complementarity to produce robust aggregates/modules. Such a theory is therefore important, because the formation of complementary (symmetric or asymmetric/chirality) modules

within complex systems can prune out huge numbers of unfeasible possibilities at each step of the hierarchical modular assembly.

3. *A qualia jump² theory*: Mathematics generally treats either scalar quantities or vector quantities (statically defined), but not the transformation of scalar to vector (dynamic type transitions). However, some properties of biological systems involve transformations from pure scalar to pure vector quantities (and vice versa): e.g. a chemical neurotransmitter signal (scalar diffusion) becomes a directional electrical signal (a vector).
4. *A hidden morphology theory*: the linkage between form and function.

The mathematical challenges involved in attempting to model biological form-function interactions are far from trivial. Natural selection attempts to optimize forms to carry out particular functions, but since novel functions evolve from existing forms, these formal attempts may be seriously limited. On the one hand, we do not have geometrical tools that can easily model processes such as the complex folding of proteins or chromosomes, or detailed embryological development. Mathematical forms share little with the actual biological processes that give rise to these structures. The mathematical abstractions currently used in system biological models generally do not illuminate the processes that give rise to biological geometries, but only their outward forms despite the work of René Thom (1994). What is interesting about biological forms, however, is not their geometry per se, but the ways in which these forms are *reifications of the biochemical processes* which they carry out or make possible. For example, it has become evident that the folding of chromosomes is a prerequisite to bringing together genes that would otherwise be spatially separated; and also that spatial proximity permits the rapid diffusion and control of interactive gene products that would otherwise be unable to interact in a reasonable biological time frame across an unfolded genome (Junier et al., 2010). Similarly, in human developmental biology we have now excellent data concerning the sets of genes that must be turned on and when they must be activated or inactivated in order to produce proper embryological development, yet the *discrete information* generated from combinations of individual genes is expressed as a *continuous flow* of proteins and hormones that produce gradients which must be reified as organized groupings of cells that have a specific form. So embryology is also stymied by the lack of mathematical approaches that can link discrete, continuous and geometrical information simultaneously. But what kind of mathematical notions would make it possible to model simultaneously the effects of geometry (spatial structure) on continuous functions such as diffusion that in turn regulate on-off gene regulatory switches that act discontinuously or digitally? And how can a mathematical object obtain and maintain its identity? Also, Lewontin has stressed the *reciprocal relationships between genes, organisms and their environment*, in which all three elements act as both causes and effects (Lewontin, 2002). Therefore, we should be able to explore alternative avenues to traditional unidirectional genotype–phenotype relationships such as cyclic or helical or chaotic genotype–phenotype mappings.

¹ Any given cell must have chromosomes, but their number can vary (as they do in cancers and parthenogenesis) and still be viable; they can have many ribosomes and mitochondria or but a few and still live; they can accumulate certain amounts of toxins or lose a certain amount of key ions and still function; etc.

² A quale is an individual instance of subjective, conscious experience, "an unfamiliar term for something that could not be more familiar to each of us: the ways things seem to us" (Dennet, 1988).

2. Are there any solutions in sight?

In fact, such biologically relevant mathematical concepts providing the base for realizing the scenario in the previous section *do* currently exist. The above questions reflecting work by Root-Bernstein (2012a) were raised with reference to a 'classical' view on the different domains of mathematics. This traditional view on mathematics has been modified with the introduction of more unified and 'relational' approaches, such as category theory (Mac Lane, 1998) and algebraic geometry (Felix et al., 2008) in general, as noted by Hoffman (2013). In addition, richer Bayesian, contextual models, but also quantum models (Gomez-Ramirez and Sanz, 2013; Kitto and Kortschak, 2013; Gabora et al., 2013), and post-Turing computation (Siegelmann, 2013) and elaborate forms of logic (Goranson and Cardier, 2013; Marchal, 2013) have changed the understanding about the role of mathematics in biology. The following two sections recapitulate two complementary approaches which touch on the implementation of the Integral Biomathics strategy of Simeonov et al. (2012b).

2.1. Category Theory (CT), Memory Evolutive Systems and Relational Biology

Category Theory (CT) is a *formal domain* of mathematics at the frontier between mathematics, logic and meta-mathematics. It provides conceptual means for thinking about mathematics in terms of the relations between its domains. CT is: i) a language which tries to uncover and unify the operations made in different mathematical branches (such as abstract algebra, topology, geometry, etc.); ii) a philosophy, which provides a general notion of mathematical structure (e.g. category of sets, of groups, of graphs, of fields, of rings, etc.); and iii) a *mindset* providing new tools (such as adjoint functors, colimits, etc.) that are useful for defining models of complex systems.

Whereas the question 'Can we model this with differential equations?' is a valid one with a yes/no answer, the answer to 'Can CT provide tools to handle this?' is often "yes" as long as we phrase the particular category-theoretic descriptions appropriately. But this affirmative answer is due to the generality of CT and means also that it is not sufficient as such for modeling things 'concretely'. One must still use a specifically suited subbranch of mathematics, although casting the problem directly in the language of category theory is also often useful. Category Theory offers a 'relational mathematics' emphasizing the relations between objects rather than the objects themselves. Indeed an object of a category is characterized not by its 'ontological structure', but by the set of morphisms arriving at it (Yoneda Lemma), which corresponds to the different operations in which the object participates. Therefore, there is no need for a new kind of set theory (Question 1), but a whole variety of morphisms can be used instead of simple maps, thus giving a much more representational freedom. For instance, we may take a category whose objects are molecules, and the morphisms model chemical interactions between them. We can look at a molecule as the set of its atoms and their chemical bonds. However, the morphisms between molecules do not correspond to maps between these sets but represent emergent properties at the molecular level depending on quantum level properties with infinitely many elements.

Two category-theoretical approaches are of particular interest for us: Memory Evolutive Systems, MES (Ehresmann and Vandbremer, 2007; Ehresmann, 2012) and Relational Biology, RB (Louie, 2009, 2013), with the latter forming a continuation of Robert Rosen's work on the subject (Rosen, 1958a,b, 1959, 1991, 1999) and on anticipatory systems (Rosen, 2012). Both represent

domain-specific incarnations of CT for biology as synergetic syntheses of a number of mathematical theories (partially ordered sets, lattices, graphs, categories, adjacency matrices, and interacting entailment-type networks, etc.).

More specifically, the MES theory can handle the different problems with self-emergent objects in the following way:

1. A "self-emergent object" is modeled as a *colimit* emerging via a complexification of an appropriate category. Examples are given in Ehresmann and Vanbremer (2007).
2. MES are particular state-transition systems. A component of the system (for instance, a cell) is not represented by a unique object but by the family of its (infinitely many) successive states. Indeed, in an MES, the original system is not modeled by a unique category but by an evolutive system, that is, a family of categories indexed by time with transition partial functors applying between them. Thus, a component C can be modeled using the family of its successive states. This representation allows one to differentiate between the complex identity (or "class identity") of C and the individual identities of its lower level components.

Second, complementary assembling (Question 2) is allowed through the consideration of "activator links" in memory from a molecule to the procedure, which consists in attracting the complementary molecule.

The qualia jump theory (Question 3) is related to hierarchy and emergence, whereby the Multiplicity Principle plays an important role since it allows for the emergence of new properties (represented by complex links). For instance, the electric signal at the cell level is an emergent property from a pattern of chemical signals acting on the molecular level.

The "hidden form" problem (Question 4) refers to the emergence of a higher-layer object as the colimit of a pattern of interacting lower-layer objects (which forces its geometric form). The key question remaining in all cases is how to implement the colimits empirically.

The RB approach presented in *The Reflection of Life* (Louie, 2013), a domain-specific CT for biology, is formulated in terms of *set-valued mappings*. Instead of considering a mapping of the form $f: A \rightarrow B$ (from set A to set B, sending element $a \in A$ to element $f(a) \in B$, Louie suggests the new correspondence $F: A \multimap D$ or $F: A \dashv [D$ (from set A to subsets of D, sending an element $a \in A$ to set $F(a) \subset D$); particularly consequential hereby is the case when $D = H(B, C)$ (the hom-set $H(B, C)$, a set of mappings from set B to set C). By using the theory of set-valued mappings it is possible to handle the above questioned four issues about living systems (1–4), of the point/set hierarchy, of continuity/discreteness, and of cyclic/helical entailment with much naturalness and ease. Ultimately, the theory of set-valued mappings culminates in the so-called imminence mapping, which greatly facilitates the further investigation of functional entailment in complex relational networks. In short, both MES and RB provide truly integrative, both multi-scale, multi-temporality mathematical approaches to the modeling of biological phenomena. Their common problem remains that they need to be translated into a more understandable and computable language, that is an "operational semantics", to handle the implementation of their concepts.

2.2. The Wandering Logic Intelligence (WLI)

A recent study presented in the 2012 Oxford seminar on the conceptual foundations of system biology (Bard et al., 2013) has put forward two essential principles of modern biology:

1. *Feedback between the participants at several levels – with oscillations being inherent* in the dynamics of this feedback in order to guarantee stability. This rule defines the “first law of system biology”: Any complex biological event involves activity at many levels and the properties that emerge from this activity are not necessarily predictable (Kolodkin et al., 2012).
2. *No level of preferred status exists*, with necessary and important events taking place at and between each level so that causality occurs upwards, downwards and within levels (Noble, 2012, 2013). This rule has been shown for being realized within the entire physiome (genome, proteome, interactome) (Werner, 2005; Shapiro, 2013). An open question here is how we can address *supervenience*⁴ (Kim, 1984, 1987).

These two principles and two additional ones, related to the emergence of the self and the complementarity requirements presented in section 1, are epitomized by the Wandering Logic Intelligence (WLI) theory (Simeonov, 1999; Simeonov, 2002a,b,c):

1. Multidimensional Feedback
2. Pulsating Metamorphosis
3. Self-Reference
4. Dualistic Congruence

They were successfully tested in practice for the specification and implementation of mobile computing and communication architectures (Simeonov, 2002c, Wepiwe and Simeonov, 2005a,b). These principles can be used also for the investigation of interacting living systems (Louie, 2013) from both the internalist and the externalist viewpoint, i.e. the 1st and 3rd person perspectives (Rössler, 1987, 1998; Matsuno, 1989, 1996). This can complement the categorical formalization of MES with the computational semantics of WLI whereby both are mutually reflective.

Into this context fall two recent insights by Matsuno (2013) and Salthe (2013). The first is about the necessity to elaborate and include a new kind of active temporal logic, which internalizes the description of the metabolic dynamics of a living system recursively *into* the dynamics itself. This temporal dynamics⁵ of the organism (or machine⁶) maintaining its own identity (from a 1st person perspective) can be modeled in terms of a *constant updating* of the present perfect tense into the present progressive tense. The second constructive aspect of this computational dynamics and operational semantics type description comes from the macroscopic level (3rd person perspective) and requires one to trace it both spatially, within sets of nested hierarchies, and temporally across the entire development cycle.

The synergies between MES and WLI were already studied in (Ehresmann and Simeonov, 2012). Both theories taken together appear to provide a sound base for the modeling of biological systems.

3. What are the foundations we build on?

Integral Biomathics strongly endorses the following topics for research in biology:

1. A source of current methodological problems in system and molecular biology lies in a preoccupation with the quantitative methods and a *disregard for the qualitative, structural approach* (Schroeder, 2013).
2. The problem of *combinatorial complexity*⁷ when dealing with large dynamic multi-protein complexes in living systems leads to the insight that conventional modeling approaches (like differential equations) fail to describe the self-assembly process, mainly due to the combinatorial explosion of the number of intermediate complexes (Tschernyschkow et al, 2013). Here a hierarchical levels approach could be a solution.
3. *Category theory* is a powerful means to express and discover new syntactic properties different from all others currently considered in biology (Cazalis, 2013).
4. *Algebraic geometry shows that form follows function*. In order to be properly understood, this requires one to take into account the interaction between form and function. The expression “ $G \times M \rightarrow M$ ” encapsulates this relation between structure and function.⁸ It is the task of biologists to provide the particular structure of the parameter group G that is involved in a biological phenomenon. In regard to the traditional distinction between *pure* mathematics and applied mathematics reflected in the expression $G \times M \rightarrow M$, G can be anything (from graphs to categories), and M can be anything from a module to a category. In view of the tremendous variation that biology offers, choices must be made in the application of mathematics to particular biological phenomena. Hereby algebraic geometry or ‘rational homotopy theory’ can prove to be essential to understanding the structure-function map in biology (Hoffman, 2012, 2013; Felix et al., 2008).
5. *Biocomputation and temporality*: It turns out that computation as now performed is unnatural in biology. Computations conceived in first-order logic are generally *not decidable*. This fact implies that there is no guarantee that such an algorithm can lead to an effective procedure to decide upon membership in a legitimate domain of discourse, or on an allowed set of formulas using Boolean true or false values.⁹
6. *Development and decidability*: A crucial question here is whether and how *decidability* is implemented in the developmental process of biology. The current practice of employing simulations in biology without examining the possibility of undecidability is a bit ill conceived. What makes a developmental process maximally challenging from the point of view of computation is whether or not decidability¹⁰ can be obtained (Salthe, 2013).

⁴ The term “supervenience” was suggested by Kim to denote such phenomena as moral properties that supervene on natural properties, or mental characteristics that supervene on physical characteristics (e.g. the properties of our nervous system). The term can be defined as follows: For two sets of properties, A (the *supervenient set*) and B (the *subvenient set* or *supervenient base*), A supervenes on B just in case there can be no difference in A without a difference in B. Reversing this principle delivers the converse concept of *antisupervenience* or *determination*: B determines A just in case sameness with respect to B implies sameness with respect to A. Hence supervenience and determination are two sides of the same coin.

⁵ Expressed through the constant exchange of its constituent molecules by new ones from its environment.

⁶ In the post-Gödelian definition of (Marchal, 2013).

⁷ Tschernyschkow et al. show how to apply a novel rule-based modeling approach in space to the study of the formation of the inner kinetochore structure that plays a central role in chromosome segregation and cell division. The pertinent simulation experiments require unconventional mathematical and computational methods for their interpretation. Structure clustering, information theory, phylogeny, and visualization have been applied so far. The challenges laid open in the present article document the need for new mathematical and computational approaches in order to tackle the combinatorial complexity of living systems in space.

⁸ Often biological form is changing during actions.

⁹ This is the satisfiability problem (SAT) within the frame of non-deterministic Turing-machine computation, which is crucial with regard to the likelihood of P vs. NP completeness (Cook, 1971).

¹⁰ Either from formal logic, or from bare empirical facts by way of an act of measurement.

7. *Use of probabilities*: The limitations of traditional or standard mathematical statistical models including the standard Bayesian approach, for modeling biological systems require the revision in terms of the *inverse* problem to models and parameter values being obtained by measurements. Here new methods such as a truly Bayesian approach (Gomez-Ramirez and Sanz, 2013) are suggested as effective tools to deal with biological probabilities e.g. in neuroscience¹¹ and physics.
8. *Realism and fractalization*: A resolution of the dichotomy between the one-person and third-person description of systems requires a subtle account of the interaction between multiple-time scales to rigorously describe complex internal (first person) experiences modeled externally (from a third person's perspective) as hierarchical nested events (Vrobel, 2013).
9. *Objectivism and contextuality*: There is a general problem in using the Newtonian Paradigm in the study of life. Specifically there is the difficulty of defining *units of selection* (Salthe, 2008) in biology,¹² where this concept plays a fundamental role. This is an unavoidable consequence of the need to take into account the *context* of whatever biological process is considered. This applies already on the molecular level when interaction between parts of the genome are considered, and on a larger scale when genotype–phenotype interactions are important. A reason for the failure of elements of the Newtonian Paradigm applied in the study of life are the two concepts of an *object* and *objectivity*. This problem was proposed to be fixed by introducing a kind of contextual mathematics using three aspects of Quantum Field Theory (QFT): potentiality in terms of multiple stable lowest energy states, spontaneous symmetry breaking and Nambu–Goldstone emergence, to explain the creation of new biological objects and structures (Kitto and Kortschak, 2013). However, a tough problem lurking here is how to secure the right fundamental predicates for the intended enterprise.
10. *Quantum-like potentiality in evolution*: A new mathematical framework for preadaptation that defines the state of a trait as a linear superposition of basic states – or possible forms – is presented here as mutually orthogonal weighted eigenvectors in a complex Hilbert space, into which a trait could evolve. The choice of trait changes is expressed as an adaptive quantum function, which plays the role of the observable (Gabora et al., 2013).

The realization of quantum-like potentiality in evolution (Gabora et al., 2013) in combination with other seminal ideas like the contextuality concept (Kitto and Kortschak, 2013), the framework of the cognizer-system model (Nakajima, 2013) or the full Bayesian approach (Gomez-Ramirez and Sanz, 2013), or the formal categorization of the individual (Cazalis, 2013), or the form-follows-function mapping of algebraic geometry (Hoffman, 2013) and the third person expression of the internal fractalization of time (Vrobel, 2013), are all consistent with the line of thought developed in the INBIOSA project (Simeonov et al., 2012a,b). These approaches are far from being congruent but we believe that they provide a much-needed new focus that predictably entails a significant “cultural exaptation”.

4. What are the potential application domains?

The above enumeration of areas of application addressed by Integral Biomathics techniques is incomplete. For example, the

WLIMES approach (Ehresmann & Simeonov, 2012) is capable to develop a robust computational framework on top of a qualitative formal model of living systems based on an evolutionary category theory in the domain of personalized medicine addressing such fields as:

- virology/vaccinology
- molecular genetics
- oncology
- neuroscience
- immunology
- emergency medicine

Characteristic of these domains is the multi-layered nature of the phenomena. Key features of these domains are that they are data and knowledge intensive fields, and beset by incomplete and noisy information. Infection biology and in particular *neuro-virology* combine a number of key systemic themes in the above 6 areas: the interactions between organisms and their environments, and those between two living systems. One of the challenging questions that can help better prevent the spreading of infections and pandemic diseases is understanding how viruses move within hosts, e.g. from the skin to the nervous system (Zaichick et al., 2013) and thereby attack multiple weak points in an organism's defense system.

5. How are these challenges being approached today?

Today, scientists use a multiplicity of mathematical and computational approaches based on the classical line of Turing machine models. None of the challenges facing the formalization of living systems outlined in Section 1 have been addressed so far (Woese, 2004; Simeonov et al., 2011). There are two main fields for theoretical research in biology and medicine:

- quantitative modeling: ODE/PDE systems, probabilistic/statistical/stochastic (e.g. Monte Carlo, Markovian, Bayesian etc.) models
- qualitative modeling: discrete state-transition systems such as Boolean/logical networks, Petri nets, process algebras (CCS, CSP, ACP, LOTOS), etc.

A third field is concerned with the visualization of experimental/empirical evidence:

- regulatory charts/maps/graphs, 3D VR models, simulation and animation, etc.

The combination of these areas is known as “hybrid modeling”. Basically we distinguish between the hypothesis-driven (qualitative) and the data-driven (quantitative) approaches, both using visualization methods to validate their models, yet with (almost) no links between them. The funds spent for carrying out data-driven research (Human Genome Project, Human Brain Project, etc.) exceed by orders of magnitude those for exploring hypothesis-driven research.

5.1. Qualitative vs. quantitative models

An important current limitation of quantitative methods is the deficit in detailed quantitative information about the reaction kinetics (kinetic and their associated parameters) underlying the protein–protein and protein–DNA interactions (Alm and Arkin, 2003).

¹¹ Neuroscience has the ‘coarse to fine’ trope (making a subsumptive hierarchy).

¹² This issue is about the *nature of identity* of a material body encountered in biology.

The missing data are usually replaced by the use of probabilistic and statistical methods. For instance, (Wierling et al., 2012) propose to predict the disturbances induced by targeted cancer therapies on the EGF signaling network by introducing a Monte Carlo type strategy incorporating repeated simulations with parameter vectors sampled from an assumed random distribution with subsequent statistical significance testing. They demonstrate the applicability of this approach by generating statistically reproducible predictions of potential drug targets.

Since the application of standard statistical models in biology is limited, refinements of the heuristics are suggested to fill this gap (Nakajima, 2013; Gomez-Ramirez and Sanz, 2013). On the other hand, the predictive power of qualitative approaches like Boolean networks and other discrete techniques is limited to qualitative conclusions only.

The majority of work done up until now has been on modeling complex molecular networks. A large body of work was done in quantitative modeling using systems of differential equations (Omholt, 2013) and in qualitative approaches based on discrete state-transition systems, e.g. by using Petri nets (Heiner and Gilbert, 2013). However, progress in these areas was limited. This is partly because we know little about the reaction constants and partly because the nature of the most interactions between the participating proteins has yet to be elucidated qualitatively or quantitatively. We cannot even be sure, for example, that the law of mass action holds true given the small number of proteins within a cell, so that models require stochastic or “negotiation” elements.

5.2. Consequences

The data driven approach in biology has not held its promise of predictive diagnostics and personalized medical treatment (Ahn et al., 2006; Gomez-Ramirez and Wu, 2012). The extensive knowledge of the genome sequences of human beings and various pathogenic agents has led to the identification of but a limited number of new drug targets (Drews, 2003). The employment of new methods for drug discovery based on strategies like high-throughput screening, combinatorial chemistry, genomics, proteomics and bioinformatics does not currently bring forth the expected new medications and therapies (Kubinyi, 2003; Glassman and Sun, 2004). A number of biotechnological projects such as gene therapy, stem-cell research, antisense technology and cancer vaccination have failed to deliver the expected results (Glassman and Sun, 2004). The common problem with many of these innovative techniques is that the risks and unwelcome side effects have been underestimated, as was the case for gene therapy (Williams and Baum, 2003). Therefore we presently give preference to the qualitative, hypothesis-driven approach, considering science to be not only concerned with producing predictive model but also and more prominently to be involved in *understanding* Nature, as René Thom argued in defense of his notion of qualitative mathematics (Thom, 1977, 1994).

6. Why can we do better than before?

Current approaches to complex problems rely on modeling but one aspect of the problem with but one form of mathematics, switching from one to another sort of mathematics to address the next aspect and then to a third one to describe yet another. All this switching is an indication of how inadequate our mathematical tools (ODE/PDE systems, stochastic models, discrete state-transition systems, etc.) of to date are. Biological systems function at all of these levels simultaneously, so why cannot our mathematics do the same? It is not biology that is too messy to be

modeled, but our mathematics is inadequate because we are not creative enough (Hong, 2013) to adequately address these biological problems.

This shows we need to go beyond the standard paradigm of computation as formally implemented in the Turing machine. One candidate to help us get out of the current stifling situation is to pay more attention to the Turing oracle machine.¹³ This is a formal scheme to address the issue of making decisions that would consistently survive on the most concrete and particular level in our empirical world. Note that the source data of biology come from concrete particulars without exception.

Remember that hierarchy theory (Salthe, 2012) suggests that reductionism can never explain how novel properties and processes emerge. Biological entities have properties that differ from chemical and physical ones and require developing appropriate mathematical notions. What we need is not more detailed physical models of biological systems that could handle larger and larger amounts of detailed data from increasingly fine-grained studies of the components of biological systems, but ways of identifying the biological properties that are as unique to such complex aggregations as temperature is to a set of molecules (Root-Bernstein, 2012a). This is why we need a new biomathematics – a mathematics based on such fields as category theory and algebraic geometry which treats continuous functions, sets, vectors, fields and other formalisms in a single complementary framework that is truly *integrative*: A unique evolutionary mathematical and computation platform that deals with the emergence of organization from non-random selection amongst replicating variations within complex populations of things. The challenge of Integral Biomathics is to provide the mathematical and computational methods necessary for the modeling of such emergent properties and organization.

7. What is missing in current theoretical biology?

Besides the often-referred to self-organization principles (Camazine et al., 2003), biological systems exhibit the following special characteristics which have been neglected by virtually all qualitative and quantitative, approaches so far:

- **Emergence:** Emergent properties differ from resultant properties that can be predicted from local lower-layer information. They resist premature attempts at being predicted or deduced by explicit calculation. Thus, the behavior of biological systems cannot be understood or predicted by simply analyzing the structure of their constituents. The latter interact in many different ways including multiple negative feedback and feed-forward controls, which lead to dynamical properties that cannot be adequately predicted by using linear mathematical models that disregard cooperation, competition, and non-additive effects. Therefore, in recognition of the complexity of informational pathways and networks, non-classical mathematical formalisms are necessary for modeling such systems

¹³ An oracle is a machine, which computes a single arbitrary (non-recursive) function from naturals to naturals (Turing, 1939). In other words, this is just another name for non-trivial meta-level heuristics that lies outside an object-level theory. In Integral Biomathics, we regard “oracles” to truly lie beyond the object-level (scientific and/or mathematical) theories, such as group theory and QM. In other words, an oracle is anything that *is or can lead to* a true statement that cannot be reached within a formalized (syntactic) system of the pertinent theory. Oracles are part of all human knowledge that cannot be proven within any of the *currently known* formal systems; i.e. they contain “true” statements that cannot be proven in a Gödelian sense. All our theories are bound to remain incomplete, but as they become richer and richer, what once lied outside a given theory will become part of the (again still incomplete) new theory.

(Aderem and Smith, 2004; Root-Bernstein, 2012a). [In our project we are going to model emergence both in an explicit and in an implicit way, i.e. (a) by developing new formalisms and (b) by using simulations, without any explicit reference to the emerging properties.¹⁴] Emergence theory regards the natural world as organized in terms of hierarchies that have evolved over time (Pattee, 1973; Salthe, 1985; Salthe and Matsuno, 1995; Kim, 1999; Morowitz, 2002; Salthe, 2012). Whereas reductionists defend an 'upward causation' by which molecular states bring about the higher-layer phenomena, the proponents of emergence advocate a 'downward causation' by which the higher-layer systems influence lower-layer ones. Indeed, there are three versions of downward causation: weak, moderate and strong (Andresen et al., 2000). We adopt a combination of the moderate accent of downward causation (Bickhard and Campbell, 2000; Lemke, 2000; Bickhard, 2004; Salthe, 2012) requiring a process ontology and the "inside-out" causation concept of Sydney Brenner (Brenner, 2010) in the context it is represented by Denis Noble (Noble, 2008, 2012). However, further details with respect to the boundary constraints (incl. non-holonomic ones), in particular when making morphogenetic decisions (Section 8.3), need to be elaborated. The only way to anticipate emergence in the Waddington-Thom-Salthe sense and in accord with Schelling's philosophy (Gare, 2013) is to observe and trace the pattern formations and their relations *within their own context at possibly multiple layers* below, at and above the layer of their initial emergence.

- **Robustness:** Biological systems tend to be impervious to less than drastic changes in their environment because they are able to adapt and have *flexibly redundant* components and pathways that can act as backups if individual components or paths fail (Csete and Doyle, 2002; Kitano, 2002; Ehresmann and Vanbremeersch, 2007).
- **Hierarchical Modularity:** Biological systems are hierarchically organized with subsystems being physically and functionally isolated in such a way that a failure in one module does not spread to all other parts of the structure with possibly lethal consequences (Alm and Arkin, 2003). This modularity, however, does not prevent different compartments from communicating with each other (Weng et al., 1999).
- **Organisational Closure and Openness:** Biological systems are self-contained with internally coupled pathways, but exchange matter, energy and information with their environment and are therefore not in thermodynamic equilibrium (Yoshiteru, 2009; Mossio and Moreno, 2010).
- **Contextuality:** Biological systems are extremely complex and dependent on their local contexts and their embedding within other systems and ecologies (Aerts and Gabora, 2005; Cardinale and Arkin, 2012; Kitto and Kortschak, 2013).
- **Complementarity:** There is a chemical link between biological structure and function ("structure follows function"). First, molecules that bind to each other almost always alter each other's physiological effects; and conversely, molecules that have antagonistic or synergistic physiological effects almost always bind to each other. Second, contemporary biological systems contain an embedded *molecular paleontology* based on small, molecularly complementary modules/subunits that are built into contemporary macromolecular structures such as receptors and transporters. Third, complementary modules

are conserved and repurposed at every stage of evolution. Finally, modularity based on molecular complementarity produces a means for storing and replicating information. Linear replicating molecules such as DNA or RNA are not required to transmit information from one generation of compounds to the next: compositional replication is as ubiquitous in living systems as genetic replication and is equally important to their functioning. Chemical systems composed of complementary modules mediate this compositional replication and give rise to linear replication schemes. Molecular complementarity plays a critical role in the evolution of chemical systems and resolves a significant number of outstanding problems in the emergence of complex systems. Most physical and mathematical models of organization within complex systems rely upon nonrandom/deterministic linkages between components. Molecular complementarity provides a naturally occurring nonrandom linker. More importantly, the formation of hierarchically organized stable modules vastly improves the probability of achieving self-organization. In addition, molecular complementarity provides a mechanism by which hierarchically organized stable modules can form. Complementarity is ubiquitous in living systems, because it provides the physicochemical basis for modular, hierarchical ordering and replication necessary for the evolution of the chemical systems upon which life is based (Root-Bernstein and Dillon, 1997; Root-Bernstein, 2012b). Recently, Kolodkin et al. (2012) argued for replacing the tradition of Occam's razor in science (reflecting the intention to model systems as simply as possible) with a 'law of completeness'.

While already taking into account hierarchical organization and modularity, the reductionist agendas of molecular and systems biology in the past ignored such essential characteristics of living systems as emergence, robustness, complementarity and contextuality. This restriction had a profound impact on biological and biomedical research during the past 50 years. For instance, the flexible redundancy (cf. robustness) is at the base of the MES' Multiplicity Principle (MP). It means, so in Edelman's "degeneracy" (Edelman and Gally, 2001), that the same output can be generated by structurally and functionally different components and pathways. The latter are *hidden (potential)* for the researcher a priori due to the switching off of a particular known component or path (e.g. an enzyme that triggers the synthesis of an undesired protein). This principle is a new key insight for understanding such phenomena as cancerogenesis and MODS.¹⁵ It needs thorough consideration when developing future personalized medical therapies. In this way there exists a functional interdependence, not only between robustness and complementarity but also among the other characteristics of living systems. This requires a higher layer of functional modeling addressing the above issues.

In most theoretical biology models the following holds true:

- data-driven and hypothesis-driven models are decoupled,
- all space-scales of interest are non-integrated,
- either upward or downward causation is used alone (generally upward),
- no self-* properties are addressed.

Therefore, current models are incomplete; they are sensitive to noisy or missing data and lack expressiveness. In addition, the

¹⁴ For instance the shape of a galaxy can be derived by simulation (most models apply Newton's law or variants thereof) over a large number of "particle" stars. The shape of a galaxy then is implicit in Newton's law.

¹⁵ Multiple Organ Dysfunction Syndrome.

modeling environments have no embedded intelligence. As a result, the experimenter/researcher is confronted with an *exponentially growing complexity* that results from a huge number of variables and parameters to explore. In addition, he/she faces *incomplete and noisy data*. The ease of data collection has exacerbated the need of models rich enough to explain relations present in the data. But model selection must be perceived as an integral part of data analysis (Johnson and Omland, 2004).

Theoretical biology has been focusing largely on dynamics, stochastic processes and discrete mathematics. Nevertheless, neither graphical pathway maps, nor “ODEs or formal programs can indicate whether a description is complete in the sense that it mirrors the full complexity of reality with ... its alternative pathways. Even if it predicts a correct observation, we are not to know whether the description is correct; we merely know that it is a possible solution. It is not obvious that there is any way of handling the depths of biological complexity...” (Bard et al., 2013). Now the time is ripe to rethink the foundations of biological and medical discovery. Our proposal is intended to overcome these shortcomings.

8. The way ahead

The following paragraphs outline our approach for realizing the objectives of Integral Biomathics within a research project in a specific application domain (cf. Section 4).

8.1. What do we suggest?

In Krakauer et al. (2011) the authors plead that it were profitable to explore a wider range of mathematical ideas, such as those connected with logical formalisms, category theory and a variety of frameworks supporting concepts related to information-processing (e.g. info-max assumptions) and forms of distributed decision-making. Hoffman’s last article in this issue suggests algebraic geometry (Felix et al., 2008) as a promising theory to tackle the problems of formalizing living systems (Hoffman, 2013).

These clarion calls are in line with the Integral Biomathics program (Simeonov, 2010; Simeonov et al., 2012a,b). As a first practical step towards the realization of this vision, we propose to devise a more moderate, but integrative and evolutionary methodology. This includes the development of a prototype for a unified framework in biomathematics and biocomputation to explore morphogenesis, development, evolution and brain function across multiple domains and perspectives.

This unified research and development framework comprises the following elements:

- Qualitative and quantitative modeling
- Deterministic and stochastic approaches
- Discrete and continuous specifications
- Formal and empirical validation and verification
- Visualization tools supporting both the understanding of the target biological system and the optimization of cognitive exploration processes

The cognitive exploration toolset supports the following research strategies:

- Focus/Intention (goal-driven research)
- Hypotheses & Deduction (combining data and model-driven inferences)
- Introspection & Retrospection
- Anticipation & Discovery
- Learning & Articulation

Our approach addresses directly three of the 23 DARPA challenges for mathematics¹⁶:

- i) The Mathematics of the Brain,
- ii) The Dynamics of Networks, and
- iii) The Fundamental Laws of Biology

Six other challenges on this list are also indirectly addressed in our discussion circle. Following previous studies carried out in the INBIOSA project¹⁷ (Simeonov et al., 2011; Simeonov et al. 2012a,b) and the follow-up activities such as this special issue of JPBMB, we are suggesting an innovative multi-layer approach for qualitative modeling and simulation of living systems based on the integration of three complementary approaches:

- a formal mathematical methodology based on a dynamic category theory, called Memory Evolutive Systems, MES (Ehresmann and Vanbremeersch, 2007).
- a formal virtual computation and communication methodology based on temporal logic, called the Wandering Logic Intelligence, WLI (Simeonov, 2002a,b), and
- a morphogenesis-based framework for generating multi-scale models of complex systems (Siregar et al., 2003).

It represents a formal framework, capable of describing, tracing and predicting the emergence and development of biological structures, using recursive specification and validation in terms of their abstract syntax and operational semantics.

A first effort to estimate the match and the benefits of unifying the first two approaches was made in the WLIMES concept (Ehresmann and Simeonov, 2012). Later, in discussions with other colleagues, we realized that an appropriate integration of structural visualization techniques for representation, discovery and validation/verification, as well as the implementation of modern programming paradigms, into our tailored qualitative approach is crucial for its success. The major advantage of our approach is that it tries to mimic “the human capacity to combine concepts in new ways or redefine one concept by re-examining it in the context of other concepts” (Van Regenmortel, 2004; Hong, 2013).

Most importantly, we are going to provide complementary 1st and 3rd person system descriptions¹⁸ using a Turing Oracle Machine (TOM) implementation in the WLI¹⁹ formalism, thus bridging the gap between the formal and informal/narrative/visual modeling systems²⁰.

Of course, such a system description addressing a challenging question like understanding the movements of viruses within the host organism (Zaichik et al., 2013) also implies a context (Kitto and Kortschak, 2013). The latter needs to be considered from a much broader perspective²¹ (Gabora et al., 2013; Gare, 2013), which is of interest for further research.

¹⁶ <https://www.fbo.gov/spg/ODA/DARPA/CMO/BAA07-68/packages.html>.

¹⁷ EC FP7 Grant number 269961, www.inbiosa.eu

¹⁸ agent-based simulations could be held to be first person.

¹⁹ To our knowledge, there is no current theory, computational framework, or applied field such as system biology in which oracles or meta-level decision rules are used to model living systems in their full complexity.

²⁰ Applying mathematics is analogical and metaphorical. Mathematical modeling in the future will have to combine both digital and analogical computation, as well as some narrative/visual form of concept expression. Some parts of it will have to be in situ in the medium being investigated, rather than operating in an abstract Platonic world outside the real world we are living in and investigating.

²¹ Incl. evolution, ecology, society and the researcher engaging in scientific inquiry, theorizing, measuring and communicating results as part of the context being investigated.

One *necessary prerequisite* to making fields like neurovirology work under a Turing oracle machine design, is to get *first hand observational data*. Once the data become available, we can evaluate the performance of a TOM at our disposal. Finally, this research framework is intended to interface to third party observation, modeling and data analysis techniques such as those used in other quantitative approaches (Wierling et al., 2012).

8.2. Perspectives

Recently, non-mainstream mathematical theories have gained a renewed interest thanks to their application to biological systems, e.g. in modeling heartbeat patterns with groupoids (Stewart, 2004), or cognitive processes using category theory (Philips et al., 2009; Philips and Wilson, 2010). Simultaneously, there was also some work discussing the chances which biology offers for the creation of new mathematical theorems (Cohen, 2004; Sturmfels, 2007; Clairambault, 2012). The case is no different with the here discussed MES and RB. In view of the capabilities presented by CT and RB, we do not really need a new type of mathematics, but rather appropriate ways to specify the biological problems using CT along the lines of MES and RB that in turn allow the artful selection and integration of appropriate mathematical theories in a workable theoretical framework. Hereby the central issue is the accurate specification of biological problems using insightful and creative techniques while switching between different fields of mathematics and biology to ask for key questions, much as Laplace did with physics and chemistry two centuries ago (Root-Bernstein, 2012a; Hong, 2013). But what if we need a mathematical theory (such as the one about self-emerging objects discussed above) that questions the axiomatic foundations of some recognized mathematical theory within the domains of life sciences and medicine, but cannot be addressed by CT (yet)?

In particular, this was the case with using geometry in physics in Einstein's GRT which required use of a non-Euclidian geometry. Such foundations were known by that time thanks to the works of Gauß, Bolyai, Lobatschewsky and Riemann. But what if we do not have such a base to reflect biological phenomena? Many physical theories were created in simultaneity with developing the mathematics required for representing them. Both disciplines were working hand-in-hand for decades, and the bonds became tighter and tighter with each new theory. Today some scientists have difficulties to classify M-theory (string theory) or gauge theory as a mathematical or a physical theory. It represents a kind of synthetic product of both domains. Now, biology is asked to follow the same way. But where would this lead us to?

Gödel's theorems delivered the proof for the necessity to downgrade the paradigm of the axiomatic basis of mathematical completeness (Hilbert's dream). Mathematical biologists (Rosen, 1991, 1999; Louie, 2009, 2013) argue that such phenomena as impredicativity (self-referencing definition) are unique for biological systems when compared to physical ones. Fuzziness in biology is another concept not easy to handle with available mathematical tools applied in physics. According to Gödel, CT/MES/RB and WLI are also incomplete theories. What does this imply?

Mathematics is not omnipotent. It needs to be developed and applied accurately in other domains of knowledge (including the humanities and art). In particular, CT is a domain of mathematics (not a 'new mathematics'), which encompasses graphs, groups, posets, etc. and thus allows for some unification of mathematics. INTEGRAL BIOMATHICS should be also an extended mathematical domain, developing and integrating mathematical and computational notions well adapted to the problems of biology.

MES and RB were developed in this spirit, but many problems remain, in particular the relations with computations that we try to model using WLI. These issues are parts of our research schedule.

Concluding all this, the important metaphorical lesson to be learned from Gödel's Incompleteness Theorems is that "nothing works for everything". Thus in the context of mathematical biology and Integral Biomathics, all one can ask for are more suitable kinds of mathematics and computation (than, e.g. Newtonian dynamics and Turing machines²²) to describe biological phenomena. But whatever it is (the tools of RB, MES and WLI included), there will always lie something outside its expression powers. There will always be some kind of entity to place in the system description as a placeholder for the unexpected (Simeonov et al., 2012b). This entity (a 'homunculus', a 'Maxwell daemon' or a 'Turing oracle') could probably be captured to some extent when given a specific focus with using the complementary 1st, 2nd and 3rd person system description perspectives (Matsuno, 2003) as borders of knowing.

We consider science to be not only concerned simply with producing predictive models, but also and more primordially be involved in *understanding* Nature, as Thom argued in defense of his notion of qualitative mathematics (Thom, 1977, 1994). Nevertheless this observation does not mean that we have to stop doing research here. Each time we have accurately identified a problem and its complementary uncertain part, we will have to find something else, another mathematical or computational formalism, to cross the next bridge when we come close to it, as others did long before us. In sum, all we can say is that we are committed to using CT, MES, RB and WLI as our tools for now. And let's see how far they will take us.

8.3. Some comments on morphogenesis

A particular characteristic of autopoiesis (Maturana and Varela, 1980) and self-organization (Kauffman, 1993; Müller and Newman, 2003), which is of special interest today, because it represents the emergent, material aspect in biology, is morphogenesis²³ (D'Arcy Thompson, 1917). Indeed the classical works of Rashevsky (1940) and Turing (1952) on reaction-diffusion systems, as well as the more recent ones of Nüsslein-Vollhard²⁴ and Gierer and Meinhardt²⁵ made a substantial progress for understanding this phenomenon. However, there are still some gaps related to the topological properties of living systems that require special attention within the concept of a "bounded autonomy of levels (BAL)" (Mesarovic and Sreenath, 2006). We can regard them as fractions of the elusive "Turing oracle" machine-representation discussed in the previous section. Particularly, there are two aspects that need to be considered in a realistic model about the emergence and development of life reflected in morphogenesis:

First, an organism constantly realizes/computes morphological symmetries throughout its developmental cycle. The external environment/ecosystem tends to interfere with these form-inducing functions, which a healthy and young system repairs again and again to restore its structure and functioning. Simultaneously, internal aging processes evoke degeneration of organs

²² Note: Using a Turing Machine (TM) as a metaphorical model for biology is inappropriate, but using Turing's notion of a Universal Machine (TUM) to define a mathematical biology, which is not based on the TM design, but on Church's thesis is a reasonable approach (Marchal, 1992).

²³ Essentially, morphogenesis is the result of the dynamics of functions. What we are interested in is to explore how the interaction of these dynamic functions can be used/visualized in the potential application domains of Section 4.

²⁴ <http://www.eb.tuebingen.mpg.de/nc/research/departments/details/details/cnv.html#1>.

²⁵ <http://www.eb.tuebingen.mpg.de/research/emeriti/hans-meinhardt/pattern7.html>.

and tissues at its own pace (related to an intrinsic metabolic rate). Both internal and external factors constantly cause symmetries to be broken. In this regard, morphogenesis reflects the capability of a living system to unfold and maintain symmetries, while opposing incompatible changes (that are also the outcome of symmetry breakings) and actively fighting deterioration at the price of using-up energy. Topology is capable of expressing the characteristics of symmetries to be embodied, although it is incapable of delineating the route from the degenerated symmetries back to the symmetry-breaking points. On the other hand, differentiable maps, which are necessary to account for singularities (at the basis of Thom's "catastrophe" theory for a dynamic explanation of morphology), are capable of deciphering whatever dynamics is proceeding in smooth manifolds, but incapable of securing the occurrence of abrupt symmetry-breaking events. Yet, both topology and differential geometry are incapable of dealing with the perpetuation of an inexhaustible degeneracy of symmetries to be broken.

Therefore, what could be further developed to handle symmetry breaking of degenerative processes from topological perspective is the inclusion of concepts rooted possibly in the "laws of form" calculus (Spencer-Brown, 1972) and incorporating perhaps ideas from differential geometry (Kühnel, 2005), group and symmetry theories (Carter, 1997; McWeeny, 2012), knot and braid theories (Moran, 2000; Kauffman, 2006), Temperley-Lieb algebra (Abramsky, 2008), as well as quantum topology and computation (Kauffman and Baadhio, 1993; Pachos, 2012), even supersymmetry (LaBelle, 2005) and beyond, all within a unifying dynamic category-theoretical-computational framework such as the one discussed in this paper. The above fields are all related to morphology, but the list is only illustrative, emphasizing the necessity to explore the details of the spatio-temporal processes.

Of course, other mathematical domains can be also useful for this purpose. Besides, symmetry breaking of degenerative processes should not be handled from a purely 'static' topological perspective as in the fields referred above, but through dynamic cascades of fractures (desynchronizations), which force successive complexifications for repair, as this is the case in MES (Ehresmann and Vanbreemsch, 2007).

Second, what is required for delivering a realistic model of developing life forms is the construction of a material body as a computational agent inside those hypothetical "protogerms" that is able to maintain its own identity while constantly suffering a breaking of the symmetries latent in itself. This material body "keeping its self-identity upon variability"²⁶ can be regarded as the primitive (bio)computational element or engine: the *vir*.²⁷ The living cell itself, or its ingredient macromolecules (including DNA/RNA complexes) are, in fact, the resulting computational assemblies – the "clusters" and "clouds" built from the operation of such multiple primitive machines (*viri*). On the other hand, premature aging, infections (such as those caused by viruses, fungi and bacteria) and degenerative/metabolic disorders can be seen as biological entities with (distributed) computations performed by *exo-viri*²⁸ provoking structural and functional organic changes in the opposite direction towards deterioration, deformation, dysfunction and death. Both analogous biocomputational mechanisms, the ones of (eso-)viri and of *exo-viri*, concur inside the organism and in the

ecosystem as a whole. Nevertheless, *senescence* entails a natural, inevitable end of life (Salthe, 2013); see, however, also (Kloeden et al., 1990).

Finally, the key issue remaining to be discovered and formalized in morphogenesis is how *decision making* in these opposite biocomputational processes and *senescence* is implemented, in contrast to the scheme suggested e.g. by Gierer and Meinhardt which (according to some interpreters) imposes an arbitrary boundary condition of hypothetical origin. It is one thing to consider the role of topology in morphogenesis, but quite another to see what aspect of the system is responsible for making morphogenetic decisions. This issue could be resolved using topology and geometry backed e.g. by category theory and algebraic geometry, and some sort of biocomputational logic such as those discussed in Simeonov (2002a,b) and Goranson and Cardier (2013) explaining the dynamics of the underlying processes.

Other approaches are capable to combine abstract theory and inference with simulation. The Generic Modeling and Simulating Platform (GMPS, Siregar, 2008) is such a fractal-like model-based system that combines "static" theories and reasoning with dynamic simulations. The static domain embodies two isomorphic and parallel worlds: a world of (nested) objects and a world of (nested) cognitive agents perceiving and acting upon the nested objects. The simulation environment computes the dynamic behavior of the objects described in the static domain. The cognitive level incorporates hypothetico-deductive patterns and can embody Turing Oracles, as well as theories such as CT and RB. The simulation environment includes self-descriptive qualitative models, discrete cellular automata, continuous deterministic and stochastic models (Siregar et al., 2003), as well as combinations thereof. Issues, related to differential geometry and topology, have been also addressed in the context of model-generation (Siregar, 2000). The GMSP is designed to study the self-organization and morphogenesis of complex systems that includes – but is not limited to – living organisms. As in any complex system, causality is modeled as top-down, bottom-up and within level co-dependencies. One of the main lessons learned so-far with the exploitation of this system is the necessity to incorporate *multi-level feedback loops* such as those identified by the WLI's First Principle (Simeonov, 2002a,b) with their own temporal and spatial frames in order to deal with two seemingly opposite situations that operate during embryogenesis: i) short-term and local identity preservation, and ii) medium to long-term identity changes. Other necessary characteristics of the system include multi-modal interactions (e.g. biochemical, mechanical, electrical) and their time-varying co-dependencies.

As a result, the *co-generation* of highly complex multi-scale and anisotropic structures and functions of living tissues can be obtained. Within this framework we have been analyzing the underlying correlates/causes of symmetry and symmetry-breaking. It appears that only integrated modeling, not limited to a single domain (e.g. chemistry or topology) can provide plausible explanations. Finally, some practical but *necessary* issues such as parallel computing need to be addressed to model the ubiquitous concurrencies operating in living systems (Passerat-Palmbach et al., 2011; Caux et al., 2010; Caux et al., 2011).

Of course, all of this goes without saying that understanding the dynamics of biology does require something *invariant* in its own descriptive enterprise, just as the dynamics of physics does. What is relevant exclusively for biology is the **occurrence of functions, which keep forms invariant** throughout the exchange of the component materials (Matsuno, 2013), and **which, in spite of their different temporalities, are able to interact collectively for maintaining the class identity of the whole over time**, thus allowing its adaptation to environmental changes.

²⁶ The object addressable in 3rd person description is actually being upheld in 1st person description (Koichiro Matsuno, June 12th 2013, personal Correspondence).

²⁷ man, hero, man of courage (Lat.); this element actually corresponds to the level 0 components of a MES (Ehresmann and Vanbreemsch, 2007), but includes also the possible concomitance and operation of a "Turing oracle" machine within itself.

²⁸ A pathogen such as a virus infecting an organism can incorporate such an *exo-vir* body.

9. Summary

This paper presented an updated survey of the most important questions in the new field of Integral Biomathics and outlined an approach of how to address them within a model-based framework. As fundamental problem of the field remains the investigation of the complex transition from micro to macro, from local to global and from statics to dynamics.

There are two key questions in this context:

1. How a unified whole, an organism with its specific morphology, can *emerge* from the competitive interactions between more or less interconnected local functions/forms, each with its own temporality?
2. How this whole can maintain its complex identity and possibly *develop* and *evolve* over time?

In fact, this is the problem that initially led to the development of MES, which still stumbles on the non-computability of the interplay among co-regulators, an open issue to this moment.²⁹ Indeed, at a local level, the function creates the form³⁰. Efficient mathematical or/and computational models have already been developed for specific functions and more are expected to come. But how this happens at the global level?

The local functions/forms, each one operating within its own temporality, are more or less interconnected across levels. Hence, the core “gluing” problem we face in Integral Biomathics has two sides: i) how the operations of these local functions can be harmonized so that the morphology (and identity) of the living entity is maintained in spite of the always occurring degeneracies, and ii) how these functions can possibly change to allow for more adaptation? It requires the examination of the interconnections between the system components on different levels, which is essentially expressed in the interactions between different functions/forms acting at different timescales. The analysis of this problem will allow to investigate how cascades of dysfunctions/fractures/degeneracies (as in MES aging theory) can be controlled to preserve the global complex identity, or how they can alternatively lead to a systemic disease, or even death, if not repaired on time. This strategy is along the line of the WLIMES approach (Ehresmann and Simeonov, 2012) to handle such kind of problems.

Acknowledgments

We would like to thank Koichiro Matsuno, Stanley N. Salthe, Otto E. RöSSLer, Arran Gare, Andree C. Ehresmann, Aloisius H. Louie, Bruno Marchal, Ted Goranson, Louis H. Kauffman and Robert S. Root-Bernstein for their valuable help with reviewing and commenting on this paper. It has passed multiple peer reviews and reformulations (from individual 1st, through shared 2nd into consolidated 3rd person descriptions) to hopefully offer a semi-formal proposal implementing the requirements of a progress report in the field.
